Abstract

Cosmic-ray photons above 10^{19} eV can convert in the geomagnetic field and initiate a preshower, i.e. a particle cascade before entering the atmosphere. We compare the preshower characteristics at the southern and northern sites of the Pierre Auger Observatory. In addition to a shift of the preshower patterns on the sky due to the different pointing of the local magnetic field vectors, the fact that the northern Auger site is closer to the geomagnetic pole results in a different energy dependence of the preshower effect: photon conversion can start at smaller energies, but large conversion probabilities ($> 90\%$) are reached for the whole sky at higher energies compared to the southern Auger site. We show how the complementary preshower features at the two sites can be used to search for ultra-high energy photons among cosmic rays. In particular, the different preshower characteristics at the northern Auger site may provide an elegant and unambiguous confirmation if a photon signal is detected at the southern site.

1 Introduction

Substantial fluxes of cosmic-ray photons at ultra-high energy (UHE), above 10^{19} eV, are predicted by non-acceleration (top-down) models of cosmic-ray origin (for example, see [1]). At a smaller level, UHE photons are also expected

* *Correspondence to:* P. Homola (piotr.homola@ifj.edu.pl)

to be produced in acceleration (bottom-up) models [2]. UHE photons can be detected through the particle cascades they initiate in the atmosphere. So far, upper limits on the photon flux were set [3,4,5,6,7]. The large exposure expected to be collected during the next years, in particular by the Pierre Auger Observatory [8], will enormously increase the sensitivity for detecting UHE photons [7].

Contrary to the case of hadron primaries, UHE photons around 10^{20} eV can interact with the magnetic field of the Earth before entering the atmosphere [9]. This process is commonly called geomagnetic cascading or preshower and leads to a dramatic change of the air shower development for primary photons [9,10,11,12,13,14].

The probability of magnetic e^+e^- pair production (“photon conversion”) and, in case of conversion, the synchrotron emission by the produced electrons depend on the particle energy and on the transverse component of the local magnetic field [15,14]. Photon conversion can occur at altitudes up to several thousand kilometers above the ground, i.e. well above the atmosphere (~ 100 km altitude). A preshower consists mostly of the secondary photons emitted by the electrons. A secondary photon of sufficiently high energy may additionally convert in the magnetic field and produce another electron pair. The number of preshower particles depends on the specific conditions and can fluctuate strongly; it can range from a few particles to a few thousand. Nevertheless, as we demonstrate in this paper, the preshower formation can be fairly well inferred from characteristics of the observed extensive air shower. The spread of the preshower particles in transverse distance from the shower axis and in arrival time at the atmosphere is well below the resolution of current shower experiments [14]. Hence, also in case of geomagnetic cascading, the subsequent air shower would be observed as one event by the experiments.

Since the probability of photon conversion and the synchrotron emission spectrum depend on the local transverse magnetic field, characteristics of the preshower process (such as conversion probability, or the energy spectrum of the preshower particles) depend strongly on the specific trajectory through the magnetosphere. For a given experimental site, this leads to a large directional dependence of preshower characteristics within the local coordinate system of zenith θ and azimuth ϕ . In addition, as already noted in the work of McBreen and Lambert 25 years ago [9], a dependence is expected on the location of the experiment: experimental sites at different geomagnetic latitudes have different local magnetic field conditions, which can affect preshower characteristics for UHE photons.

The comparison of preshower characteristics of UHE photons expected at two sites located at different hemispheres of the Earth is of particular current interest due to the construction of the Pierre Auger Observatory. The southern part

of the Observatory (“Auger South”) is situated near Malargue (Argentina) at 69.2° W, 35.2° S. The construction of Auger South is approaching completion and first results were obtained, including an upper limit to UHE photons [7]. To achieve full sky coverage, the northern site (“Auger North”) is planned in Colorado (USA) at 102.7° W, 37.7° N. At Auger South, the magnetic field of $\sim 24.6 \mu T$ points upward to $\theta \sim 55^\circ$, $\phi \sim 87^\circ$. At Auger North, the magnetic field of $\sim 52.5 \mu T$ points downward from $\theta \sim 25^\circ$, $\phi \sim 262^\circ$.¹

Previous works in the literature focused rather on the directional dependence of preshower characteristics of UHE photons for one given site than comparing the conditions at different sites. Examples of magnetic field strengths at various sites were given in [11]. In that work, the observable of shower size (total number of electrons at ground) was studied. It was noted that azimuth regions of smaller (or stronger) preshower effect can be identified that may differ between the sites. In [12], the altitude dependence of the transverse component of the magnetic field was compared for the two Auger sites for a few directions, and preshower particle spectra were studied. E.g. in [13], it was pointed out that at Auger North, due to the larger magnetic field, the preshower effect starts at a lower energy. A particular focus of that work was the study of observables for the ground array, where differences in the detector signals for converted and unconverted primary photons were found.

In this work, making use of our `PRESHOWER` code [14] linked to `CONEX`, a fast shower simulation program [16], we perform a dedicated comparison of the preshower characteristics of UHE photons for the conditions of the Auger North and Auger South sites. The geomagnetic field in `PRESHOWER` is described by the IGRF model [17,18]. We find that the transition range in energy from small to large conversion probabilities is larger at Auger North, starting at smaller but ending at higher energy. We study how the differences of the preshower characteristics between the two sites can be used to perform a complementary search for UHE photons. In particular, the situation may arise where a possible UHE photon signal detected at Auger South requires an independent cross-check. As will be shown, such a cross-check could come from Auger North. In fact, making use of the UHE preshower effect by observing from a different experimental site seems the most elegant and natural way for cross-checking an UHE photon signal claim.

While the study is performed for the specific case of the two Auger sites, the general findings hold for any two sites with sufficiently different local magnetic field conditions. The results shown for Auger North hold, to a good extend, also for the HiRes [19] and Telescope Array [20] sites, both of them being located in Utah.

¹ Azimuth is defined in this work counterclockwise from geographic East. For instance, $\phi = 0^\circ$ means East, $\phi = 90^\circ$ North etc.

The plan of the paper is as follows. In Section 2, preshower features are discussed, and in Section 3, the corresponding air shower features are studied. In Section 4, UHE photon scenarios and their observation at the two different sites are investigated. In particular, it is worked out how observations at the two sites can complement each other. Conclusions are given in Section 5. In Appendix A it is shown how the transverse component of the geomagnetic field in the IGRF model varies along different particle trajectories. In Appendix B we show a collection of conversion probability sky maps supplementing Section 2.1.

2 Comparison of preshower features at Auger South and North

2.1 Conversion probability

A key parameter to characterize the fate of an UHE photon in the Earth's magnetic field is the conversion probability P_{conv} . Given the local differential probability of a photon to convert into an electron pair, P_{conv} results from an integration along the particle trajectory. Small values of P_{conv} indicate a large probability of the UHE photon to enter the atmosphere without conversion and to keep its original identity. In turn, UHE photons would almost surely undergo geomagnetic cascading for values of P_{conv} close to unity.

P_{conv} depends on the experimental site, the photon energy, and the direction of the particle trajectory in the local coordinate system of zenith θ and azimuth ϕ , $P_{\text{conv}} = f(\text{site}, E, \theta, \phi)$. Thus, for a chosen site and a fixed primary photon energy, sky maps within the local coordinate system $P_{\text{conv}} = f(\theta, \phi)$ can be produced to study the pattern of UHE photon conversion.

As an example, in Figure 1 sky maps are shown for two different energies $\lg(E/\text{eV})=19.6$ and 20.0 , corresponding to ~ 40 EeV and 100 EeV, both for Auger North and South (sky maps at various energies between $\lg(E/\text{eV})=19.4$ and 20.4 are collected in Appendix B). One can see that at 40 EeV, photon conversion is already important at Auger North for a large part of the sky. In contrast to this, at Auger South conversion is very unlikely for 40 EeV photons independent of their arrival direction.

The energy above which photon conversion becomes important, is expected to be smaller at Auger North due to the larger local magnetic field strength. To quantify this, we show in Figure 2 a sky map of photon energies for a fixed conversion probability of $P_{\text{conv}} = 10\%$. It can be seen that photon conversion starts at a factor ~ 2 higher energy at Auger South compared to Auger North.

Fig. 1. Sky maps of conversion probabilities at $\lg(E/\text{eV})=19.6$ (left) and 20.0 (right) for Auger North (AN, top), Auger South (AS, middle), and the difference (AN–AS, bottom). Contour lines are given for the conversion probability (top and middle rows of plots) with a stepsize of 10%, and for the difference of conversion probabilities (bottom plots) with a stepsize of 20%. Azimuthal directions are labeled (“E” for East etc.). Zenith angles are given as concentric circles of 10° steps ($\theta = 0^\circ$ in the center). The pointing direction of the local magnetic field vector at ground is indicated for a specific site (top and middle plots).

At energies of 100 EeV, also for Auger South photon conversion is important for a sizeable part of the sky (Figure 1, right). As expected, small conversion probabilities are found for sky regions around the pointing direction of the local magnetic field vector. Thus, we expect significant differences in P_{conv} between the two sites for a given direction in terms of local coordinates, with the difference being strongly dependent on the regions of the sky. Also shown in Figure 1 (bottom plots) are therefore sky maps of the *difference* in P_{conv}

between Auger North and South for the two fixed energies. While for the larger part of the sky, P_{conv} is larger at Auger North (due to the stronger field), there is at 100 EeV a significant part of the sky where P_{conv} is larger at Auger South (due to the different pointing of the magnetic field vector).

It is clear from this that cuts on the local shower arrival direction can be introduced to select regions of the sky where P_{conv} is larger (or smaller) at one site compared to the other site. Applying the same cuts to data from the two sites, event sets with enriched (for the one site) and depleted (for the other site) fractions of converted (or unconverted) photons can be prepared. A possible photon signal could then show up with *different* signatures at the two sites for the *same* selection cuts. This will be studied in more detail in Section 4.

Another feature is showing up in Figure 2 where sky maps of energies are plotted for fixed P_{conv} . The range of energies covered (for the same value of P_{conv}) is larger at Auger North than at Auger South. For instance, the energy at which $P_{\text{conv}} = 10\%$ is reached changes at Auger North by a factor ~ 15 over the sky, at Auger South only by a factor ~ 4 . In other words, the sky pattern for geomagnetic cascading is more “inhomogeneous” at Auger North (larger transition range in energy from small to large conversion probability) than at Auger South.

In fact, while the preshower effect starts at smaller energies for a larger part of the sky at Auger North, the transition range to full conversion extends to even *higher* energies at Auger North, see Figure 2 (bottom), sky map for $P_{\text{conv}} = 90\%$. As an example, a 250 EeV photon ($\lg(E/\text{eV})=20.4$) has a conversion probability $> 40\%$ for all directions at Auger South, while at Auger North a small window with $P_{\text{conv}} < 10\%$ still exists (see Figure B.3).

At first glance this seems unexpected. As the magnetic field strength is a factor two larger at Auger North, one would rather expect photon conversion at smaller energies at Auger North. However, this feature is again related to the different locations within the geomagnetic field, with Auger North being considerably closer to the magnetic pole: in this case, the local magnetic field lines are less curved when following them from ground to higher altitudes. Correspondingly, the *transverse* projection of the magnetic field vector, which determines the local conversion probability, remains small out to considerably larger distances from the Earth compared to the situation at Auger South. Thus, the fact that Auger North is closer to the pole results in a larger transition region for photon conversion, starting at smaller energies compared to Auger South (due to the *larger strength* of the local magnetic field) and ending at higher energies compared to Auger South (due to the *smaller bending* of the magnetic field lines with distance).

Fig. 2. Sky maps of photon energies for fixed conversion probabilities of 10% (top), 50% (middle) and 90% (bottom) for Auger North (left) and Auger South (right). Contour lines are given with a stepsize of $\Delta \lg(E/\text{eV}) = 0.1$. Values of the minimum and maximum energies are assigned to the lines (in $\lg(E/\text{eV})$). See caption of Figure 1 for further explanations.

To summarize, the different positions of the sites in the geomagnetic field translate into a spatial shift of the conversion patterns at the sky according to the pointing of the local magnetic field vector and into modifications of the transition energy range. The modifications of the transition energies are not a simple shift but also the size of the energy range is affected.

Fig. 3. Average energy spectrum of preshower particles, weighted by particle energy (converted events only) for 10^{20} eV photons. Chosen are two directions, one at each site, with the same integrated conversion probability $P_{\text{conv}} = 50\%$. Direction 1 (Auger North): $\theta \sim 60^\circ, \phi \sim 270^\circ$, direction 2 (Auger South): $\theta \sim 66^\circ, \phi \sim 150^\circ$.

2.2 Particle energy spectra in converted showers

Here we check to what extent it is sufficient to consider only the difference in conversion probability when comparing the two sites. For a given energy, two different directions with the same integrated conversion probability P_{conv} correspond to different spatial trajectories through the magnetosphere. One could imagine in one case a relatively small transverse magnetic field extending over a larger distance, while in the other case relatively close to the Earth, a stronger magnetic field contributes. The same integrated conversion probability could be reached, but the spectrum of preshower particles may differ (for instance, the synchrotron emission spectrum gets harder with stronger magnetic field).

In Figure 3, averaged spectra of preshower particles at the top of the atmosphere are shown, weighted by the particle energy, for different directions at Auger North and South. In both cases, $P_{\text{conv}} = 50\%$. One can see that both spectra look quite similar; most energy is carried by particles of $\sim 10^{19}$ eV. A shift between the distribution of about a factor 1.6 in energy can be noted, however. Performing air shower simulations for these two directions, a difference in the average depth of shower maximum X_{max} of the converted events of $\sim 20 \text{ g cm}^{-2}$ is obtained. This difference is much below the shift in X_{max} comparing converted and unconverted photon showers to each other (see next

Section). For other directions of same integrated conversion probability, differences are typically smaller than shown here. For our purposes in this work, we conclude that the differences in conversion probabilities are a sufficient measure for the different preshower characteristics when comparing the two sites.

3 Air showers initiated by converted and unconverted photons

In this section, we study the basic features of air showers initiated by converted and unconverted photons, with particular emphasis on the *differences* between these two classes of events. The reasoning is that the differences between Auger South and North in the sky patterns for photon cascading, studied in the preceding Section, translate into differences of the air shower features that are well observable.

It is well known that unconverted showers, contrary to converted, have a considerably delayed shower development due to the LPM effect [21]. Additionally, event-by-event fluctuations can be extraordinarily large due to a positive correlation of the suppression of the cross-section with air density (a photon traversing a certain depth ΔX without an interaction has a larger probability for traversing an additional ΔX due to the larger air density).

In Figure 4, examples of shower profiles are shown for 10^{20} eV primaries. Simulations are carried out with CONEX, which reproduces well CORSIKA [22] results. The extrapolation of the photonuclear cross section is based on the fit by the Particle Data Group [23]. All primaries arrive from the same local direction, in this case from geographic North at 45° zenith. The photon conversion probability is large at Auger North ($> 99.9\%$) and small at Auger South (0.4%). Consequently, most of the photons at Auger North convert and have a depth of shower maximum $200\text{--}300\text{ g cm}^{-2}$ smaller than the (mostly unconverted) photon showers at Auger South. As expected, also fluctuations are much smaller at Auger North in this example. The corresponding distribution of depth of shower maximum X_{max} from simulating 1000 events for the conditions in Figure 4 is shown in Figure 5 (upper panel). For the same local direction, the expected features of photon showers are very different at the two sites.

For comparison, also profiles for hadron primaries are added using the QGSJET 01 model [24]. Converted photons are more similar to protons, but still reaching X_{max} at larger depths. More relevant for the present study are, however, the differences between converted and unconverted photons.

According to the results of the preceding Section, we expect the opposite be-

Fig. 4. Examples of shower profiles (randomly selected) for 10^{20} eV photons at Auger North (solid black line), at Auger South (solid red line), protons (dashed green line), and iron nuclei (dotted blue line). For all events, arrival directions are fixed to local geographic North at 45° zenith.

havior (larger X_{max} at Auger North) for certain other directions. Results of simulations with the same conditions as in Figure 4 and in the upper panel of Figure 5, but with the azimuth changed by 180° , are presented in the lower panel of Figure 5. The angle between this direction and the local magnetic field vector at Auger North is relatively small. As expected, the X_{max} distribution of photons at Auger South is now peaked at smaller values, while the distribution at Auger North is dominated by the large X_{max} values from unconverted events.

Another important quantity to distinguish photons from hadron primaries is the muon content of the air shower. It is well known that photon showers have less muons compared to hadron-initiated ones; important for the current investigations is whether a significant difference in the muon content exists between converted and unconverted photons. In Figure 6, for the same events shown in Figure 4, the longitudinal profiles of muons are displayed. One can see a shift between the muon profiles for Auger North (all converted here) and Auger South (all unconverted here). This shift is, to a large extent, connected to the shift in X_{max} (Figure 4).

The distribution of the total number of muons at ground is given in Figure 7. As expected, fluctuations are larger in case of unconverted events, i.e. at Auger South in this example. However, average values are quite similar. Thus, differences between converted and unconverted photon showers in the number

Fig. 5. *Upper panel:* $X_{\max}$ distributions of different primaries for the same conditions as in Figure 4 (photons arriving from local geographic North). *Lower panel:* same as in upper panel, but the photon simulations were performed with the azimuth changed by 180° (photons arriving from local geographic South). If indicated, distributions were scaled.

of muons are much less spectacular than in $X_{\max}$. Part of the differences can directly be related to $X_{\max}$. We conclude that the main difference between converted and unconverted photons, and thus the main difference that could be exploited by observing from two sites, can be characterized by the $X_{\max}$ of

Fig. 6. Examples of muon profiles (randomly selected) for 10^{20} eV primaries for a muon energy threshold 1 GeV (same events as shown in Figure 4).

Fig. 7. Distributions of total number of muons at ground (energy threshold 1 GeV) for different primaries for the same conditions as in Figures 4 and 5 (upper panel) and 6. If indicated, distributions were scaled.

the shower.

There are other observables from ground arrays that were shown (or are ex-

pected) to differ between converted and unconverted photons, namely the shower size (total number of electrons at ground) [11], the curvature of the shower front and the steepness of the lateral distribution of ground particles [13], or the risetime of the detector signal at a certain distance from the shower core [7]. The differences between these observables for the two classes of photon events are closely connected to the stage of shower development and, correspondingly, to $X_{\max}$. We therefore expect, firstly, that also data from ground arrays alone, even without a direct observation of $X_{\max}$ such as from fluorescence telescopes, can be exploited to search for complementary photon signatures at the two sites. And secondly, a study of $X_{\max}$ distributions (which provides a measure of the relative shower age at ground) provides us with most relevant information for investigating possible complementary features of both sites.

4 UHE photon scenarios and their observation at Auger South and North

We now give an illustration of how advantage could be taken of the complementarity between the preshower characteristics at Auger North and South. As examples, we consider a diffuse photon signal, a signal from a source region, and the absence of photons (i.e. determining upper limits).

4.1 Diffuse photon signal

In this example, we assume an isotropic primary flux with the all-particle energy power law spectrum with index -2.84. Such a spectrum is consistent with the first estimate from the Auger South Observatory [25]. It should be noted that a deviation from this power law, for instance a suppression of the flux above the energy of the speculated GZK cut-off, would result in a correspondingly modified all-particle flux at highest energies. The existence of such a hypothetical suppression will not affect the conclusions of this section: discussed differences between photon showers observed at Auger North and South depend only on the local geomagnetic field (see below for a quantitative example of applying a simple cut-off to the energy spectrum).

We assume protons and photons as primaries. The input fraction of photons as a function of primary energy follows the results from a topological defect model in [2]. More specifically, the photon fraction is 9%, 15%, 27%, and 48% for energies above $\lg(E/\text{eV}) = 19.0, 19.3, 19.6$, and 20.0 , respectively (see also the curve labeled “TD” in Figure 8 in Ref. [7]).

For each Auger site, we simulated ~ 1000 events above $\lg(E/\text{eV}) = 19.6$ with zenith angles between $30\text{--}75^\circ$ and random azimuth. We accounted for a detector resolution of 25 g cm^{-2} in X_{max} and 10% in primary energy. The zenith angle range was chosen similar to that in the analysis of Auger data for the first photon limit [7]. In particular, near-vertical events are excluded in this example to reduce the fraction of photon events with X_{max} below ground (see also discussion in Section 4.3). The simulated event number corresponds to an observation time of about 5–8 years of the completed Auger South ground array. For a similar data taking period, data statistics of the fluorescence detectors is reduced by a factor ~ 7 .

In Figure 8 we show, as a scatter plot, the X_{max} versus primary energy. We restricted the azimuth range in this plot to the local *northern* sky by requiring an azimuth between $30\text{--}150^\circ$. In this region of the sky, photon conversion starts at Auger North at smaller energies than at Auger South. As can be seen from the Figure, there are considerably less events with large X_{max} (e.g. exceeding 1000 g cm^{-2}) at Auger North, for the same overall cuts applied to the data at both sites.

The corresponding average X_{max} and the X_{max} fluctuations as a function of energy are shown in Figure 9. Clear differences between the two sites can be noted. In particular, the larger average X_{max} at Auger South is accompanied by significantly increased shower fluctuations.

The X_{max} distribution of events (as projected from the scatter plot shown in Figure 8) is given for 50–100 EeV primary energies in Figure 10. At Auger North, the events with large X_{max} (unconverted photons, present at Auger South), are mostly lacking. Instead, events accumulate at $\sim 900 \text{ g cm}^{-2}$ (converted photons). To see the effect of a hypothetical GZK suppression of the energy spectrum at high energies, we applied a simple cut-off at $E = 80 \text{ EeV}$ ($\lg(E/\text{eV}) = 19.9$) to the data set. As expected, all the characteristic peaks of the X_{max} distribution remain at the same positions as in case of spectrum *without* cut-off plotted in Figure 10. The only difference is the heights of the peaks corresponding to converted and unconverted photons with respect to the proton peak: they decrease by 10-20% in case of spectrum *with* cut-off. This is due to the larger fraction of photons at higher energies in the assumed model.

An observation of such different characteristics at Auger North and South (signal at different values of X_{max} , behaviour of average X_{max} and X_{max} fluctuations as a function of energy), would be an unambiguous confirmation of a photon signal detection.

So far, the local northern sky was studied. As expected, a similar but *opposite* behaviour is found for the local southern sky (not shown) when selecting, for

Fig. 8. $X_{\max}$ versus energy for events arriving from the local *northern* sky (see text for definition) at Auger North (top) and at Auger South (bottom), for unconverted photons (open blue circles), converted photons (filled black squares), and protons (red dots).

instance, shower arrival directions from azimuth angles between 210–330°. Since this occurs at a somewhat higher energy, the event statistics is reduced in this case due to the steep primary flux spectrum.

Fig. 9. Average X_{max} (top) and rms of X_{max} (bottom) versus energy for the conditions shown in Figure 8, i.e. local northern sky at Auger North and at Auger South. For comparison, values corresponding to a pure proton flux are also shown using the model QGSJET 01 (dotted blue lines).

4.2 Photon signal from a localized source region

Let's now regard a hypothetical scenario of a photon signal coming from a certain source region. Localized hadron-accelerating sources are expected to produce photons at an energy typically 10 times smaller than the maximum energy of accelerated hadrons. Detection of the currently highest energy event at 3×10^{20} eV provides a motivation for the investigation of photons at not much lower energies produced by a localized source.

The sky region accessible to both Auger sites is limited to source declinations $|\delta| < \sim 53^\circ$. Requiring a maximum zenith angle of 75° for shower observations

Fig. 10. $X_{\max}$ distributions for Auger North and South at the local northern sky at 50–100 EeV (projection from the scatter plot shown in Figure 8). The different primary types (protons, converted and unconverted photons) contribute mainly to ranges in $X_{\max}$ as indicated in the plot. In particular, the peak in the distributions at $X_{\max} \sim 800 \text{ g cm}^{-2}$ comes from protons, at $\sim 900 \text{ g cm}^{-2}$ (at Auger North) from converted photons, and at $\sim 1050 \text{ g cm}^{-2}$ (at Auger South) from unconverted photons.

at both sites, the range of accessible declinations is $|\delta| < \sim 38^\circ$.

The conversion probability of UHE photons from the direction of a certain source can change with time even at one site only, depending on the source declination. Examples are given in Figure 11 for $10^{19.6} \text{ eV}$ and $10^{20.0} \text{ eV}$ photons. For instance, for a source at the celestial equator conversion probabilities between 0–75% are covered at $10^{19.6} \text{ eV}$ at Auger North.

It is interesting to note that for the same conditions, the conversion probability is negligible at Auger South. Thus, characteristic differences when observing events from the same sky region exist that again could be used for a complementary study of UHE photons. A special case is the scenario of a source region observed *at the same time* from Auger North and South. Also here, differences exist in the *instantaneous* conversion probability of photons. This can be seen in Figure 11 by comparing the curves at Auger North and South for the same source declination as a function of time. For instance, the instantaneous difference in the conversion probabilities for $10^{20.0} \text{ eV}$ photons from a source at the celestial equator can reach, in the extreme case, almost 100%. Differences exist also for sources at declinations $\delta \sim -30^\circ$, i.e. for the galactic center region (Figure 11).

Fig. 11. Conversion probability at the two Auger sites versus time (in hours, offset arbitrary) for $10^{19.6}$ eV (top) and $10^{20.0}$ eV (bottom) photons for different source declinations as indicated. The same right ascension is assumed for all sources. The heavy lines denote the time intervals during which the sources are visible at zenith angles less than 75° . For better visibility the beginnings of lines are marked with large dots.

4.3 Absence of photons

If the photon flux is below the detection limits of current experiments, upper limits are deduced by comparing the data to expectations for showers initiated by primary photons. The signatures from photon showers differ between Auger

North and South due to geomagnetic cascading. Thus, even in case of *observing no photons* at both sites, differences arise in the *analysis* of the data since the photon hypothesis tested when deriving a limit is different at each site. Upper limits obtained at Auger South can, to some extent, be cross-checked this way at Auger North.

In photon limit studies, simulations are used to optimize the analysis cuts and to calculate the acceptance to photons. Due to the generally larger X_{max} , the acceptance to photons can be smaller than that to nuclear primaries when requiring the X_{max} to be above ground. Then, an efficiency correction to the photon limit may be needed. To keep the correction small, a fiducial volume cut was applied in [7], requiring a minimum zenith angle of 35-42 deg (depending on energy).

This condition could be relaxed at Auger North due to the onset of the preshower effect at smaller energies. On the one hand, the power of shower-to-shower discrimination is reduced for events from these arrival directions, as converted photon showers are more similar to proton-induced showers than unconverted ones. On the other hand, the result is a gain in instantaneous aperture at Auger North. The effective gain is largest at energies around $\lg(E/\text{eV}) \sim 19.8$ where for a sizeable part of the sky, photons already can convert at Auger North, contrary to Auger South. For identical experiments and requiring X_{max} to be above ground, the aperture is increased at Auger North by $\sim 30\%$ (20%) when allowing zenith angles up to 60° (75°) at $\lg(E/\text{eV}) \sim 19.8$.

5 Conclusion

The difference of conversion probabilities is a convenient and effective parameter to estimate the complementarity between two sites for searching for UHE photons. Regarding the two sites of the Pierre Auger Observatory, Auger North and Auger South, significant differences in the preshower features of UHE photons exist. The sky patterns of the preshower features are shifted due to the different pointing directions of the local magnetic field vectors. In addition, Auger North is located closer to the magnetic pole. This leads to a larger transition range in energy from small ($< 10\%$) to large ($> 90\%$) conversion probabilities compared to Auger South. More specifically, photon conversion starts at Auger North at smaller energies due to the larger magnetic field, but conversion probabilities $> 90\%$ are reached for the whole sky at higher energies due to the smaller bending of the field line with distance.

These differences in the preshower characteristics result in different rates of (un-)converted photons from the same (both in local and astronomical coordinates) regions of the sky. Air showers initiated by converted and unconverted

photons can be well distinguished by current experiments. The main difference is related to the position of depth of shower maximum X_{max} , which is typically $\sim 200\text{--}300\text{ g cm}^{-2}$ smaller for converted photons.

For a variety of UHE photon flux scenarios (diffuse photon flux; photons from source regions; absence of photons), the different preshower characteristics at the experimental sites can be used for a complementary search for UHE photons. Most important, a possible detection of UHE photons at Auger South may be confirmed in an unambiguous way at Auger North by observing the well predictable change in the signal from UHE photon showers.

Fig. A.1. Transverse component of the geomagnetic field (according to the IGRF model) along various directions at two observation sites: Auger South (AS) and Auger North (AN). The directions are specified by the zenith (attached to each curve) and azimuth (the same within one plot) angles given in the local coordinate system. The local minima occur at the altitudes at which the geomagnetic field is nearly parallel to the considered directions.
